MEAN-FLUX REGULATED PCA CONTINUUM FITTING OF SDSS Lyα FOREST SPECTRA

Submitted to AJ

ABSTRACT

Continuum fitting is an important aspect of Ly\textsubscript{\alpha} forest science, since errors in the estimated optical depths scale with the fractional continuum error. However, traditional methods of estimating continuum in noisy and moderate-resolution spectra ($S/N \lesssim 10$ pixel\textsuperscript{-1} and $R \sim 2000$, e.g. SDSS) such as power-law extrapolation or dividing by the mean spectrum, achieve no better than $\sim 15\%$ RMS accuracy. To improve on this, we introduce mean-flux regulated/principal component analysis (MF-PCA) continuum fitting. In this technique, PCA fitting is carried out redwards of the quasar Ly\textsubscript{\alpha} line in order to provide a prediction for the shape of the Ly\textsubscript{\alpha} forest continuum. The slope and amplitude of this continuum prediction is then corrected using external constraints for the Ly\textsubscript{\alpha} forest mean-flux. From tests on mock spectra, we find that MF-PCA reduces the errors to $8\%$ RMS in $S/N \sim 2$ spectra, and $< 5\%$ RMS in spectra with $S/N \gtrsim 5$. The residual Fourier power in the continuum is decreased by a factor of a few in comparison with dividing by the mean continuum, enabling Ly\textsubscript{\alpha} flux power spectrum measurements to be extended to $\sim 2 \times$ larger scales. Using this new technique, we make available continuum fits for 12,069 $z > 2.3$ Ly\textsubscript{\alpha} forest spectra from SDSS DR7 for use by the community. This technique is also applicable to future releases of the ongoing BOSS survey, which is obtaining spectra for $\sim 150,000$ Ly\textsubscript{\alpha} forest spectra at low signal-to-noise ($S/N \sim 2$).

Subject headings: intergalactic medium — quasars: emission lines — quasars: absorption lines — methods: data analysis

1. INTRODUCTION

Over the past 2 decades, the Lyman-\textalpha (Ly\textsubscript{\alpha}) forest absorption observed in the spectrum of high-redshift quasars has been an important probe of large-scale structure and the inter-galactic medium (IGM) at $z > 2$. The fundamental quantity of interest of the Ly\textsubscript{\alpha} forest is its local optical depth to absorption, $\tau(x)$, at position $x$. This is not a directly observed quantity; it is derived from the flux transmission $F = e^{-\tau}$, which requires knowledge of the intrinsic quasar continuum $C(\lambda_{\text{rest}})$ in order to be extracted from the observed flux, $F = f(\lambda_{\text{obs}})/C(\lambda_{\text{rest}})$, where $f(\lambda_{\text{obs}})$ is the observed flux and $\lambda_{\text{rest}} \equiv \lambda_{\text{obs}}/(1 + z_{\text{QSO}})$ is the restframe wavelength of the quasar at redshift $z = z_{\text{QSO}}$. The error in the measured optical depth, $\delta \tau$, scales roughly with the fractional continuum error, $\delta \tau \sim \delta C/C$, which means that accurate continuum fitting is important in the optically thin Ly\textsubscript{\alpha} forest, where $\tau \lesssim 1$. Therefore, accurate estimates of the underlying quasar continuum are crucial in order to take full advantage of modern Ly\textsubscript{\alpha} forest data sets.

While virtually all aspects of Ly\textsubscript{\alpha} forest science are dependent on the continuum determination, some are more sensitive than others. For example, the Ly\textsubscript{\alpha} forest probability distribution, which is used to constrain the IGM temperature-density relation (TDR), is notoriously sensitive to continuum errors: Lee (2011) have recently found that a $2\%$ systematic error in the continuum estimation can double the errors in the TDR even with high signal-to-noise data. On the other hand, measurements of the 1-dimensional flux power spectrum $P_{F}(k)$ and other 2-point statistics (e.g. threshold clustering functions, Lee & Spergel 2011), are affected by the Fourier power introduced by intrinsic quasar emission lines in the Ly\textsubscript{\alpha} forest region. For example, the unaccounted continuum variance in the quasar continuum has limited the measurement of the 1-dimensional Ly\textsubscript{\alpha} forest flux power spectrum (McDonald et al. 2006) to comoving scales of $r \lesssim 40 h^{-1}$Mpc at $z = 2.5$. Ongoing attempts to measure the baryon acoustic oscillation (BAO) feature in the Ly\textsubscript{\alpha} forest using transverse correlations across lines-of-sight are less sensitive to continuum errors (McDonald & Eisenstein 2007); however, large continuum errors will still degrade the significance of the BAO signal measured in this fashion.

Unfortunately, accurate quasar continuum fitting is a non-trivial problem. At redshifts ($z > 2$) in which the Ly\textsubscript{\alpha} forest becomes accessible to ground-based optical telescopes, the high absorber line-density makes it challenging to identify the intrinsic quasar continuum. With high-resolution and high signal-to-noise ($S/N$) quasar spectra obtained from large telescopes, continua are usually fitted using some form of spline-fitting to the observed transmission peaks of the forest — if one believes that the transmission peaks truly reach the quasar continuum at a given redshift (but see Faucher-Gigu\`ere et al. 2008; Lee 2011). These direct-fitting methods cannot, in general, be applied to large data sets such as the Sloan Digital Sky Survey, as the modest resolution and low $S/N$ make it impossible to directly fit the Ly\textsubscript{\alpha} forest except for the very highest $S/N$ subsamples — and even then steps need to be taken to account for the degradation of transmission peaks from the lower resolution (see, e.g. Dal'Aglio et al. 2009). Moreover, direct fitting techniques usually require significant

human intervention and are often very time-consuming, precluding their application to the $\sim 10^5$ Ly$\alpha$ forest sightlines in SDSS.

Noisy Ly$\alpha$ forest data usually require some form of extrapolation from the relatively unabsorbed spectrum blueward\(^3\) of the quasar’s Ly$\alpha$ $\lambda 1216$ broad emission line. The simplest way to do this is to fit a power-law $f_\nu \propto \nu^\alpha$ to spectral regions uncontaminated by quasar emission lines redwards of Ly$\alpha$, or even to eschew fitting individual spectra and extrapolate a mean power-law from $\lambda_{\text{rest}} > 1216$Å using power-law values from the literature \cite{vanden Berk et al. 2001}, from e.g.,).

There are two major issues with power-law estimation of Ly$\alpha$ forest continua. Firstly, there is a break in the underlying quasar power-law at $\lambda_{\text{rest}} \sim 1200$Å – 1300Å. This was first identified by \cite{Zheng et al. 1997} from a study of low-redshift ($z_{\text{QSO}} \sim 1$) quasars observed in the ultra-violet, in which the Ly$\alpha$ forest continuum could be clearly identified due to the low Ly$\alpha$ line density at those epochs. A subsequent study by \cite{Telfer et al. 2002} found mean power-law indices of $\langle \alpha_{\text{NUV}} \rangle = -0.69$ and $\langle \alpha_{\text{EUV}} \rangle = -1.76$ redwards and bluewards of $\lambda_{\text{rest}} \sim 1200$Å, respectively. This implies that a naïve power-law extrapolation from $\lambda_{\text{rest}} > 1216$Å would underestimate the true Ly$\alpha$ forest continuum by $\sim 10\%$. Furthermore, \cite{Telfer et al. 2002} found a large scatter in $\alpha_{\text{NUV}}$ and $\alpha_{\text{EUV}}$ from the individual quasars in their sample, with no correlation between the two; this increases the error from power-law extrapolation in individual Ly$\alpha$ forest spectra. While \cite{Desjacques et al. 2007} and \cite{Páris et al. 2011} have discussed this EUV-NUV power-law break in the context of Ly$\alpha$ forest estimation, it is often ignored in Ly$\alpha$ forest analyses.

Secondly, the Ly$\alpha$ forest ‘continuum’ (usually defined around $\lambda_{\text{rest}} \approx 1040$Å – 1180Å) includes weak emission lines such as Fe II $\lambda 1071$ and Fe II/Fe III $\lambda 1123$, although the exact identifications vary from author to author. These emission lines can cause deviations of up to $\sim 10\%$ from a flat continuum. It is possible to take these features into account on average: for example, \cite{Bernardi et al. 2003} modeled them as two Gaussian functions superposed on top of an underlying power-law. However, there is a great diversity in the shape and equivalent width of these weak emission lines \cite{Suzuki 2006}. Therefore, the use of an average continuum shape would not account for variations of up to $10\%$ within individual quasars due the presence of these emission lines.

One possible avenue for improved quasar continuum fits is Principal Component Analysis (PCA). \cite{Suzuki et al. 2005} explored this using a sample of 50 low-redshift quasars observed in the UV by the Hubble Space Telescope (HST), in which the $\lambda_{\text{rest}} < 1216$Å continuum can be clearly identified. They concluded that while PCA fits to the red-side ($\lambda_{\text{rest}} = 1216 – 1600$Å) of individual spectrum gave a good prediction of the Ly$\alpha$ continuum shape (i.e. the weak emission lines), the overall continuum amplitude had $\sim 10\%$ errors. This is presumably due to the EUV-NUV power-law break. \cite{Páris et al. 2011} recently carried out a similar analysis on a high-S/N (S/N $\gtrsim 10$ per pixel) subsample of the Sloan Digital Sky Survey (SDSS) quasar sample. They found a better prediction accuracy of $\sim 5\%$, possibly due to their larger spectral baseline ($\lambda_{\text{rest}} \approx 1025$Å – 2000Å as opposed to $\lambda_{\text{rest}} \approx 1025$Å – 1600Å in the earlier work).

However, the standard PCA formalism does not take pixel noise into account, whereas the majority of quasars observed in SDSS have low signal-to-noise (S/N $< 10$) and have argued that PCA fitting errors scale directly with the noise level, which implies that, e.g., one can expect no better than $\sim 20\%$ continuum accuracy in a S/N $= 5$ spectrum using PCA, even without taking the power-law break into account.

For all the reasons outlined above, more accurate continuum-fitting methods are sorely needed to take full advantage of Ly$\alpha$ forest data from SDSS and future spectroscopic surveys. In this paper, we will explore a refinement of the PCA technique which we term ‘mean-flux regulated PCA’ (MF-PCA). Briefly, we carry out least-squares-fitting of PCA templates to the unabsorbed quasar spectrum redwards ($\lambda_{\text{rest}} > 1216$Å) of the Ly$\alpha$ line in order to obtain a prediction for the continuum shape, and then use the expected mean flux, $\langle F(z) \rangle$, to constrain the amplitude of the fitted continuum. \cite{Tytler et al. 2004} have shown that the dispersion in $\langle F \rangle$ expected from a $\Delta z = 0.1$ segment of Ly$\alpha$ forest at $z = 2$ is $\sigma_F(\Delta z = 0.1) \approx 4\%$. When averaged across an entire Ly$\alpha$ forest sightline (which spans $\Delta z \approx 0.4$ for a quasar at $z_{\text{QSO}} = 2.5$), one expects the continuum amplitude to be predicted to $\sim 2\%$.

This paper is organized as follows: §2 describes the publicly available SDSS quasar sample which will be the initial subject of our new technique. §3 elucidates the MF-PCA technique, which is then tested on mock spectra in §4. We will then discuss the results of our continuum fitting and future improvements. The continuum fits have been made publicly available and can be downloaded via anonymous FTP\(^4\).

\section{Data}

The MF-PCA technique which we develop in this paper is optimized towards large sets of noisy Ly$\alpha$ forest data spectra. We will apply this technique to the Sloan Digital Sky Survey data, which comprises $\sim 10^5$ Ly$\alpha$ forest sightlines at moderate resolution ($R \approx 2000$) and modest signal-to-noise (S/N $\sim$ few per pixel).

This section provides an overview of the SDSS Ly$\alpha$ forest data sample, and also the two sets of quasar templates which we will use to fit this data set.

\subsection{SDSS DR7 Ly$\alpha$ Forest Sample}

In this paper, we carry out continuum-fitting for publicly-available spectra from the final SDSS Data Release 7 (DR7) quasar catalog \cite{Schneider et al. 2010}, which is comprised of 105,783 spectroscopically confirmed quasars observed from the 2.5m SDSS Telescope in Apache Point, NM. The spectra cover the observed wavelength range $\lambda_{\text{obs}} = 3800$Å – 9200Å with a spectral resolution of $R \equiv \lambda / \Delta \lambda \approx 2000$.

From this overall catalog, we select a subsample suitable for Ly$\alpha$ forest studies. First, we require that some portion of the quasar Ly$\alpha$ forest region, $\lambda_{\text{rest}} = \lambda_{\text{rest}} \approx 1025$Å – 1600Å.

\footnote{In this paper, we use the terms ‘blue’ and ‘red’ relative to the quasar Ly$\alpha$ emission line unless otherwise noted.}

\footnote{ftp.astro.princeton.edu/lee/continua/}
Most of the sightlines have median S/λ since the extreme blue end (near 1041˚α that the majority of the Lyα distributions of our final quasar sample is shown in Figure 1. It is clear that the Lyα tailer limit. This sets a minimum quasar redshift of 3. For the quasars that satisfy this redshift criterion, we excise the portions of the spectra that lie below λobs = 3840Å. In addition, broad absorption line (BAL) quasars have continua which are difficult to characterize (although see Allen et al. 2011) for a method to recover quasar continua from BALs), therefore we discard quasars flagged as BALs in the Shen et al. (2011) value-added quasar catalog.

There are 13,133 quasars in the DR7 quasar catalog which satisfy the above criteria. We make further quality cuts by discarding 962 spectra which have SPPIXMASK = 0 or 12 maskbits set (this signifies issues with the fiber; see Stoughton et al. 2002 for further details on the SDSS bitmask system), and 2 spectra where the signal-to-noise was too low to normalize the spectra, leading to negative normalizations. This leaves us with a sample of 12,069 spectra, to which we will apply the MF-PCA technique. Within individual spectra, we mask pixels which have either zero inverse-variance or the SPPIXMASK = 0 or 28 maskbits set. This avoids the use of problematic pixels, such as rejected extractions, bright sky-lines or bad flats.

The median signal-to-noise in the sample is S/N = 3.0 per 69 km s^{-1} SDSS pixel within the Lyα forest, and S/N = 6.2 per pixel in the λrest = 1225Å – 1600Å wavelength region. The redshift and signal-to-noise distributions of our final quasar sample is shown in Figure 1. It is clear that the Lyα forest data from DR7 are noisy. Most of the sightlines have median S/N < 10 within the Lyα forest, which is too noisy to be fitted individually using existing techniques.

In addition, we need to deal with Damped Lyα Absorbers (DLAs) within the spectra. These are absorbing systems with neutral hydrogen column densities of N_{HI} ≥ 2 × 10^{20} cm^{-2} which result in complete absorption over large portions (Δv ~ 10^3 km s^{-1}) of affected sightlines. Since the MF-PCA technique (§ 3) fits the amplitude of the quasar continuum based on the mean-flux of the low column-density Lyα forest, the excess absorption of a DLA within a sightline would bias the continuum estimate.

To correct for this, we use a catalog of 1427 DLAs identified in the SDSS DR7 spectra by Noterdaeme et al. (2009). First, we mask the wavelength region corresponding to the equivalent width of each DLA (Draine 2013):

\[
W \approx \lambda_\alpha \left[ \frac{e^2}{m_e c^2} N_{HI} f_\alpha \lambda_\alpha \left( \frac{\gamma_\alpha \lambda_\alpha}{c} \right) \right]^{1/2},
\]

where \(\lambda_\alpha = 1216\) Å is the rest-frame wavelength of the hydrogen Lyα transition, \(e\) is the electron charge, \(m_e\) is the electron mass, \(c\) is the speed of light, \(N_{HI}\) is the H I column density of the DLA, \(f_\alpha\) is the Lyα oscillator strength, and \(\gamma_\alpha\) is the sum of the Einstein A coefficients for the transition.

However, the damping wings of each DLA extend beyond the equivalent width, providing a small but non-negligible excess absorption to the pixels close to the DLA. We correct for this by multiplying each pixel in the spectrum with \(\exp(\tau_{\text{wing}}(\Delta \lambda))\), where

\[
\tau_{\text{wing}}(\Delta \lambda) = \frac{e^2}{m_e c^2} \frac{\gamma_\alpha \lambda_\alpha}{4\pi} f_\alpha N_{HI} \lambda_\alpha \left( \frac{\lambda}{\Delta \lambda} \right)^2
\]

and \(\Delta \lambda \equiv \lambda - \lambda_\alpha\) is the wavelength separation in the DLA restframe.

### 2.2. Quasar Templates

![Fig. 1](image-url)
In order to predict the shape of the Lyα forest continuum, we need a set of template spectra with clearly identified continua at wavelengths $\lambda_{\text{rest}} < 1216$ Å. For this purpose, we will use two different sets of quasar templates, derived from quasars observed in the Hubble Space Telescope (HST), and SDSS itself.

Suzuki et al. (2005) derived PCA templates from 50 quasars that had been observed by the Far Object Spectrograph (FOS) on the Hubble Space Telescope in the ultraviolet. At the low-redshifts ($0.14 < z_{\text{QSO}} < 1.04$) of these quasars, the line-density of the Lyα forest is sufficiently small that the quasar continuum could be clearly identified. This enabled the creation of templates in the range $\lambda_{\text{rest}} = 1025\AA - 1600\AA$, covering Lyβ $\lambda 1025$ to C IV $\lambda 1549$.

Paris et al. (2011) recently carried out a similar study, applying the techniques in Suzuki et al. (2005) to a subsample of 78 SDSS DR7 quasars. These $z_{\text{QSO}} \approx 3$ quasars were selected to have full coverage of the Lyα forest and relatively high signal-to-noise ($S/N \gtrsim 10$ pixel$^{-1}$). The transmission peaks in the Lyα forest were hand-fitted with a low-order spline function to provide a continuum estimate. PCA templates were then derived in the spectral range $\lambda_{\text{rest}} = 1020\AA - 2000\AA$, which included the C III $\lambda 1906$ line. While this process might give a biased continuum level due to the low resolution and S/N of the templates, it should provide a good description of the relative shape of the quasar continuum which is required for MF-PCA — the mean-flux regulation process is designed to correct for uncertainties in the overall continuum level arising from pure PCA fitting.

We do not expect the redshift differences between the template and the DR7 quasars to be a significant issue, even for the Suzuki et al. (2005) quasars ($z_{\text{QSO}} \approx 0.6$). This is because various studies (e.g. Vanden Berk et al. 2004; Fan 2006) have suggested that there is little redshift evolution of quasar spectra. However, the shape of quasar spectra is known to have a significant luminosity dependence, such as the well-known Baldwin effect (Baldwin et al. 1978), which is the anti-correlation between the strength of the C IV $\lambda 1549$ emission line and the quasar luminosity. It is therefore reasonable to suppose that there would be a significant difference in the spectral shapes represented by two templates and the overall SDSS sample. This is because the Suzuki et al. (2005) sample is comprised of relatively low-luminosity, nearby quasars as opposed to the Paris et al. (2011) quasars, which were selected to have high S/N and are therefore a luminous subsample of the SDSS quasars.

In order to compare the relative luminosities, we calculate $\lambda L_{1280}$, the intrinsic monochromatic luminosity near $\lambda_{\text{rest}} = 1280\AA$, for the quasars in our SDSS DR7 sample as well as the two template samples. We assume a standard ΛCDM cosmology with $h = 0.7$, $\Omega_m = 0.28$, and $\Omega_m + \Omega_{\Lambda} = 1$. The respective distributions of $\lambda L_{1280}$ is shown in Figure 2. The SDSS DR7 quasars have a typical luminosity of $\lambda L_{1280} \approx 10^{46}$ ergs/s, while the Suzuki et al. (2005) and Paris et al. (2011) quasars are about 0.5 dex fainter and brighter, respectively. However, the combined luminosity distributions of the Suzuki et al. (2005) and Paris et al. (2011) template quasars significantly overlap the full range of SDSS DR7 quasars, which justifies the use of both templates in this paper.

### 3. Method

The mean-flux regulated PCA (MF-PCA) fitting method described in this paper is essentially a two step process: (1) fitting of the red side ($\lambda_{\text{rest}} > 1216$ Å) of the individual quasar spectra using PCA templates, to predict the shape of the weak emission lines in the Lyα forest continuum. This is followed by (2) constraining the amplitude of the predicted Lyα forest continuum to be consistent with existing measurements of the mean-flux evolution of the Lyα forest, $\langle F(z) \rangle$.

#### 3.1. Least-squares PCA Fitting

The basic concept of principal component analysis (PCA) is that a normalized quasar spectrum, $f(\lambda)$, can be represented as

$$f(\lambda) \approx \mu(\lambda) + \sum_{j=1}^{m} c_j \xi_j(\lambda),$$

where $\mu(\lambda)$ is the mean quasar spectrum, $\xi_j(\lambda)$ is the $j$th principal component or ‘eigenspectrum’, and $c_j$ are the weights for an individual quasar. The formalism for deriving the eigenspectra and weights is described in Suzuki et al. (2005) and Paris et al. (2011).

The standard PCA formalism for deriving the weights, $c_j$, does not take into account spectral noise, which renders it unsuitable for noisy SDSS spectra (see Figure 1b). Instead, we first carry out a least-squares fit to the red-side of each spectrum using the full $\lambda_{\text{rest}} \approx 1000\AA - 1600\AA$ eigenspectra as a basis. Due to the correlation between the weak emission lines within the Lyα forest and in $\lambda_{\text{rest}} \sim 1300\AA - 1500\AA$ (Suzuki et al. 2005), we expect this to provide a reasonable prediction for the shape of the continuum.

As described in §2.2, we have two separate sets of PCA eigenspectra from Suzuki et al. (2005) and Paris et al. (2011). In principle, one could combine the two sets of quasar templates to generate one set of eigenspectra.
which would encompass the diversity of both template samples. However, the template spectra from Paris et al. (2011) are not available to us at time of writing, therefore we will carry out our fitting procedure separately for the two sets of PCA eigenspectra. Suzuki et al. (2005) had found that out of their 10 principal component eigenspectra, only the first 8 components appeared to describe physical features in the spectra, while the 9th and 10th components seemed to describe mostly noise. Therefore, we will use only 8 components from each set of eigenspectra for our fits. In addition, for the sake of consistency we limit ourselves to the rest-wavelength range $\lambda_{\text{rest}} = 1020\text{Å} – 1600\text{Å}$ of each eigenspectrum even though the Paris et al. (2011) eigenspectra extend up to $\lambda_{\text{rest}} = 2000\text{Å}$.

However, we have found that fitting the SDSS spectra with just the PCA weights $c_j$ was insufficient to account for the large diversity of the sample. Therefore, we introduce 2 additional fit parameters: a power-law component, $\alpha_\lambda$, and redshift-correction factor, $c_z$. The power-law component, $\alpha_\lambda$, is necessary due to the large range of slopes found in the SDSS quasars. Even though the 3rd through 5th principal components in the HST eigenspectra include the spectral slope, they also describe some emission-line features — the introduction of $\alpha_\lambda$ as a free parameter allows an additional degree of freedom and enables a better fit to the emission lines and slope simultaneously. Due to this degeneracy between the slopes within the eigenspectra and $\alpha_\lambda$, we do not interpret the latter as the slope of the underlying quasar power-law continuum. The power-law parameter also helps account for low-order spectro-photometric errors as well as dust extinction in the spectrum.

The redshift-correction factor, $c_z = \lambda_{\text{fit}} / \lambda_{\text{pipe}}$, translates the spectrum along the wavelength axis with respect to the rest wavelength given by the pipeline redshift, $\lambda_{\text{pipe}}$, to a best-fitting rest wavelength, $\lambda_{\text{fit}}$. It is required as the SDSS pipeline redshifts are not completely accurate (see, e.g., Hewett & Wild 2010). However, due to the asymmetry and velocity shifting of quasar emission lines at different redshifts, we do not necessarily interpret

![Fig. 3. — Successful examples of our least-squares PCA fitting method on SDSS quasar spectra with different S/N. In each plot, we show the observed flux (orange), pipeline noise (green), $C_{\text{init}}$, the PCA fit from the first line-masking iteration (black dashed-line), and final PCA fit, $C_{\text{PCA}}$ (black solid line). Crosses indicate pixels which have been discarded by our absorption line-masking scheme. The vertical dashed lines indicate $\lambda_{\text{rest}} = 1216\text{Å}$ in the quasar restframe; all fitting is carried out redwards of this wavelength. The median S/N value quoted is evaluated redwards of the Ly$\alpha$ emission line, and the absolute flux error, $|\delta F|$, is defined in Equation 4. Note that the amplitude of the Ly$\alpha$ forest continuum ($\lambda_{\text{rest}} < 1216\text{Å}$) is not well-fitted by the PCA procedure, and will need to be corrected in the mean-flux regulation step (§ 3.2).]
as a true redshift correction — it is merely an ad-hoc parameter to obtain the best-possible fit to the spectrum. The full list of free parameters for our continuum-fitting procedure shown in Table 1 (\(a_{\text{MF}}\) and \(b_{\text{MF}}\) are free parameters for the mean-flux regulation step, described in §3.2).

We are now in a position to carry out the fitting procedure. First, the quasar spectrum is shifted to the quasar restframe using the pipeline redshift, and normalized at \(\lambda_{\text{rest}} = 1275 - 1285\) Å. We then use the least-squares fitting routine MPFIT (Markwardt 2009) to find the best-fitting set of parameters, \([c_2, \alpha, \sigma]\), given the spectrum and its noise. The initial fits from this procedure is represented by the black dashed lines in the examples shown in Figure 3.

However, while the intrinsic quasar spectrum is generally well-defined redwards of \(\alpha\) in the SDSS spectra, in many cases intervening metal absorption lines can be seen in the spectrum in the \(\lambda_{\text{rest}} \approx 1216 - 1600\) Å wavelength. To prevent these absorption features from biasing the PCA fitting, we carry out a simple iterative procedure to mask these absorption lines: using the continuum, \(C_{\text{init}}\), obtained from the initial least-squares fit, we mask pixels in which \(f(\lambda) - C_{\text{init}}(\lambda) < -2.5\sigma(\lambda)\), where \(f(\lambda)\) and \(\sigma(\lambda)\) are the observed spectrum and pipeline noise, respectively. We then make a new PCA fit and repeat this process until the fit converges. In Figure 3 the final PCA fits, \(C_{\text{PCA}}\), are shown as black solid lines while the masked pixels are denoted by crosses.

From Figure 3 we see that the least-squares PCA fitting procedure generally works well, even with noisy (S/N \(\sim\) few) spectra. The fit to the \(\alpha\) line in Figure 3 is then automatically considered good fits, while the rest are visually inspected and flagged for artifacts in the real data can bias \(|\delta F|\) to larger values even for good fits (we did not mask any lines when calculating \(|\delta F|\), as our metal-masking algorithm is rudimentary and sometimes masks legitimate pixels).

In practice, we carry out the PCA fitting procedure using the two different PCA templates described in §2.2 then for each SDSS spectrum we select the fit which gives the lower value of \(|\delta F|\). Fits with \(|\delta F|\) values under the 95th percentile of those from the mock spectra (red line in Figure 5) are then automatically considered good fits, while the rest are visually inspected and flagged for goodness-of-fit on the red-side of the spectrum — approximately 90% of the spectra were adequately fit. The spectra which are not well-fitted by our procedure consist mostly of objects which have strong absorption systems at \(\lambda_{\text{rest}} > 1216\) Å, such as metal absorption from DLAs and weak BAL quasars. An example of this is shown in Figure 4a. There are also quasars with unusual spectral shapes which are not represented in the template spectra described in §2.2 such as quasars with weak emission lines (Fig. 4b).

The spectra now have been had PCA fits carried out on them redwards of \(\alpha\), but the predicted continuum, \(C_{\text{PCA}}\), extends bluewards of \(\alpha\) (\(\lambda_{\text{rest}} < 1216\) Å). For the objects which are well-fitted on the red-side of the spectrum, we expect the predicted continua to provide a reasonable prediction for the shape of the \(\alpha\) continuum bluewards of \(\alpha\), but the overall amplitude is uncertain due to the EUV-NUV power-law break described in the Introduction. We now turn to the next fitting step, mean-flux regulation, to constrain the continuum amplitude.

### 3.2. Mean-Flux Regulation

In the least-squares PCA fitting step described in the previous section, we have hitherto used no information bluewards of the quasar \(\alpha\) emission line due to the absorption from the \(\alpha\) forest. However, since the absorption redshift at any point in the \(\alpha\) forest is known (\(z_{\text{abs}} = \lambda_{\text{obs}}/1216\) Å - 1), the average absorption averaged over each sightline can be used to constrain the predicted continuum. In this section, we will describe the use of the mean-flux evolution of the \(\alpha\) forest, \(\langle F(\lambda) \rangle(z)\), to regulate the amplitude and slope of the predicted PCA continuum. We refer to this as the ‘mean-flux regulation’ step.

Using the PCA continuum \(C_{\text{PCA}}(\lambda_{\text{rest}})\) fitted to the observed spectrum, we first extract the \(\alpha\) forest transmission \(F_{\text{init}}(\lambda_{\text{rest}}) = f(\lambda)/C_{\text{PCA}}(\lambda_{\text{rest}})\) in the range \(\lambda_{\text{rest}} = 1041\) Å - 1185 Å. The extracted \(\alpha\) forest is then divided into bins, and the mean-flux, \(F_{\text{init}}^{\text{bins}}(\lambda_{\text{bin}})\), is eval-

In the least-squares fitting step described in the previous section, we have hitherto used no information bluewards of the quasar \(\alpha\) emission line due to the absorption from the \(\alpha\) forest. However, since the absorption redshift at any point in the \(\alpha\) forest is known (\(z_{\text{abs}} = \lambda_{\text{obs}}/1216\) Å - 1), the average absorption averaged over each sightline can be used to constrain the predicted continuum. In this section, we will describe the use of the mean-flux evolution of the \(\alpha\) forest, \(\langle F(\lambda) \rangle(z)\), to regulate the amplitude and slope of the predicted PCA continuum. We refer to this as the ‘mean-flux regulation’ step.

Using the PCA continuum \(C_{\text{PCA}}(\lambda_{\text{rest}})\) fitted to the observed spectrum, we first extract the \(\alpha\) forest transmission \(F_{\text{init}}(\lambda_{\text{rest}}) = f(\lambda)/C_{\text{PCA}}(\lambda_{\text{rest}})\) in the range \(\lambda_{\text{rest}} = 1041\) Å - 1185 Å. The extracted \(\alpha\) forest is then divided into bins, and the mean-flux, \(F_{\text{init}}^{\text{bins}}(\lambda_{\text{bin}})\), is eval-

\[
|\delta F| = \frac{\int_{\lambda_{\text{min}}}^{\lambda_{\text{max}}} \left| \frac{C_{\text{PCA}}(\lambda) - f(\lambda)}{f(\lambda)} \right| d\lambda}{\int_{\lambda_{\text{min}}}^{\lambda_{\text{max}}} d\lambda},
\]

where \(C_{\text{PCA}}(\lambda)\) is the fitted continuum and \(f(\lambda)\) is the observed spectrum smoothed by a 15-pixel boxcar, to avoid biasing \(|\delta F|\) in noisy spectra. \(\lambda_{\text{max}} = 1600\) Å and \(\lambda_{\text{min}} = 1225\) Å represents the range over which we calculate \(|\delta F|\).

The distribution of \(|\delta F|\) in the fitted data is shown in Figure 5, which plots \(|\delta F|\) against the red-side signal-to-noise per pixel, \(S/N_{\text{rest}}\), for PCA fits to a subset of the SDSS spectra as well as the mock spectra described in §4.

Figure 5 provides a useful diagnostic for the quality of the PCA fits on the SDSS spectra. We expect the fits to the mock spectra (green crosses) to represent the case in which the PCA eigenspectra describe the spectra nearly perfectly (see §4, therefore they typically have smaller values of \(|\delta F|\) than the real spectra. Clearly, the SDSS spectra with large \(|\delta F|\) are most likely bad fits, but note that the presence of metal absorption lines and other artifacts in the real data can bias \(|\delta F|\) to larger values even for good fits (we did not mask any lines when calculating \(|\delta F|\), as our metal-masking algorithm is rudimentary and sometimes masks legitimate pixels).

In practice, we carry out the PCA fitting procedure using the two different PCA templates described in §2.2 then for each SDSS spectrum we select the fit which gives the lower value of \(|\delta F|\). Fits with \(|\delta F|\) values under the 95th percentile of those from the mock spectra (red line in Figure 5) are then automatically considered good fits, while the rest are visually inspected and flagged for goodness-of-fit on the red-side of the spectrum — approximately 90% of the spectra were adequately fit. The spectra which are not well-fitted by our procedure consist mostly of objects which have strong absorption systems at \(\lambda_{\text{rest}} > 1216\) Å, such as metal absorption from DLAs and weak BAL quasars. An example of this is shown in Figure 4a. There are also quasars with unusual spectral shapes which are not represented in the template spectra described in §2.2 such as quasars with weak emission lines (Fig. 4b).
Fig. 4.— Examples of SDSS quasar spectra in which the PCA fitting procedure fails to provide a reasonable fit redwards of the quasar Lyα line. (a) A strong proximate Lyα absorber has decimated the quasar Lyα emission line, and its associated N V+ C IV have introduced broad absorption features to the $\lambda_{\text{rest}} > 1216\AA$ fitting region — the current algorithm is incapable of masking such strong absorption features. (b) A weak emission-line quasar. The quasar templates described in §4 do not include spectral shapes such as these.

Fig. 5.— Dependence of absolute flux error from the red-side PCA fits, $|\delta F|$, against the S/N per pixel in the range $\lambda_{\text{rest}} = 1225\AA - 1600\AA$. This is plotted for random subsets of 2000 SDSS spectra (black squares) and 2000 mock spectra described in §4 (green crosses). The red line traces the 95th percentile of $|\delta F|$ in the mock spectra; SDSS spectra with $|\delta F|$ smaller than this are automatically considered good fits, while spectra above this line are visually inspected to ensure fit quality.

We use least-squares-fitting to find the values of $a$, $\alpha$, and $\beta$, in order to avoid over-fitting.

We now introduce a quadratic fitting function $\hat{F}(\lambda_{\text{rest}})$ in the manner

$$\hat{F}(\lambda_{\text{rest}}) = C_{\text{PCA}}(\lambda_{\text{rest}}) \times (1 + a_{\text{MF}} \lambda_{\text{rest}} + b_{\text{MF}} \lambda_{\text{rest}}^2),$$

where $a_{\text{MF}}$ and $b_{\text{MF}}$ are free parameters for the fit, while $\lambda_{\text{rest}} \equiv \lambda_{\text{rest}}/1280\AA - 1$. Note that for the lower redshifts ($z_{\text{QSO}} \lesssim 2.4$) in which only a limited portion of the Lyα forest is accessible, we use only the linear parameter, $a_{\text{MF}}$, in order to avoid over-fitting.

We again use least-squares-fitting to find the values of $a_{\text{MF}}$ and $b_{\text{MF}}$ which provide the best fit between the extracted mean-flux $\hat{F}_{\text{bin}}(\lambda_{\text{bin}})$ and the external mean-flux constraint $\langle F \rangle(z)$. In this mean-flux regulation step, the parameters $c$, $\alpha$, and $c_j$ fitted to $\lambda_{\text{rest}} > 1216\AA$ are kept fixed. For the mean-flux constraint, we use a double power-law fitted from the mean-flux measurement of [Paris et al. 2011], kindly provided by Isabelle Paris:

$$\tau_{\text{eff}}(z) = \left\{ \begin{array}{ll} (0.0031 \pm 0.0012) \times (1 + z)^{3.49 \pm 0.31}, & z < 3.2 \\ (0.0011 \pm 0.0012) \times (1 + z)^{4.21 \pm 0.70}, & z \geq 3.2 \end{array} \right.,$$

where $\tau_{\text{eff}}(z) = \langle F \rangle(z)$.

In principle, the errors in the continuum fit should now be at the level of a few percent, arising from some combination of the large-scale variance in the Lyα forest and errors in the fitting. In the next section, we will use mock spectra to quantify the level of continuum errors in the MF-PCA technique.

4. TESTS ON MOCK SPECTRA

The errors in the MF-PCA continuum fitting technique can be tested by carrying the above procedure on noisy mock spectra, and comparing the fitted continuum with the ‘true’ continuum which is known by construction. This testing process is also useful to check our algorithm for bugs and efficiency. In this section, we will describe the process of generating realistic mock spectra, and the quantitative results of the MF-PCA technique. We will also make a comparison between MF-PCA and the common technique of using the mean quasar continuum as the Lyα forest continuum.

4.1. Generating Mock Spectra

The first step is to create synthetic quasar spectra from PCA eigenspectra, by making Gaussian realizations of the PCA weights, $c_j$, (see Equation 3) in the manner described in Suzuki (2006). Note that this is an approximation, as the distribution of the weights may not be fully Gaussian, but it does generate realistic-looking
quasar spectra. In principle, the PCA eigenspectra used to generate the mock spectra and those used in the fitting procedure should be separate but drawn from the same distribution. While we do have two sets of PCA eigenspectra (§ 2.2), they represent quasars with different luminosities. Hence, we do not expect to be able use eigenspectra from Paris et al. (2011) to fit mock spectra generated from the Suzuki et al. (2005) eigenspectra, and vice versa. However, since we only use 8 principal components in our PCA fitting step (§ 3.1), we can generate our mock spectra using 10 principal components in order to increase the uncertainty in the fitting. Nevertheless, the tests described in this section will primarily apply to the limit in which the PCA eigenspectra are a good representation of the fitted quasars, which we have argued (§ 2.2) is a reasonable assumption.

Therefore, we generate mock quasar spectra in the spectral range $\lambda_{\text{rest}} = 1020\AA - 1600\AA$, using 10 principal components from the Suzuki et al. (2005) eigenspectra. Next, we need to introduce Ly$\alpha$ forest absorption to the mock spectra. For this, we use the publicly available Roadrunner Ly$\alpha$ forest simulations of White et al. (2010). These are N-body simulations with a box size of $(750 h^{-1} \text{Mpc})^3$ and a grid scale of $187.5 h^{-1} \text{kpc}$, in which the Ly$\alpha$ forest flux was derived using the fluctuating Gunn-Peterson approximation. The simulations were released in the form of 22,500 Ly$\alpha$ forest sightlines per box, output at redshifts $z_{\text{box}} \approx 2.00, 2.25, 2.50, \text{and } 2.75$.

For a given mock quasar at redshift $z_{\text{QSO}}$, we select the simulation box with the closest redshift, $z_{\text{box}}$. Using Equation 6, we then re-normalize the mean-flux of the box to $\langle F \rangle(z = (1 + z_{\text{QSO}})1100/1216 - 1)$, i.e. using the absorber redshift corresponding to the $\lambda_{\text{rest}} = 1100\AA$ in the quasar spectrum. We choose to normalize the mean-flux across the entire box rather than in individual spectra in order to preserve the variance across different lines-of-sight, which is a source of error in the MF-PCA continuum fitting. A random line-of-sight is selected from the set of skewers, and the transmitted flux in each pixel, $F_i$, is rescaled to $F_i' = F_i \times \langle F \rangle(z_{\text{abs},i})/\langle F \rangle(z = (1 + z_{\text{QSO}})1100/1216 - 1)$, where $z_{\text{abs},i}$ is the absorber
redshift corresponding to the pixel. This introduces redshift evolution of the mean flux, \( \langle F \rangle (z) \), within the individual sightlines which had hitherto had a fixed value of \( \langle F \rangle \).

The simulated Ly\( \alpha \) forest absorption is added to the mock quasar spectrum in \( \lambda_{\text{rest}} < 1216\,\text{Å} \), and smoothed to the approximate SDSS resolution, \( R = 2000 \). Gaussian noise is then added to the mock spectrum using the noise array of a randomly-chosen SDSS quasar spectrum with the same \( z_{\text{QSO}} \) and S/N. The mock spectra are then run through the MF-PCA fitting process described above to obtain continuum fits.

### 4.2. MF-PCA Continuum-Fitting on Mock Spectra

In Figure 6 we show several examples of the mock spectra and the fitted MF-PCA continua. The first thing to note is that mock spectra look realistic. They look similar to the real spectra shown in Figure 5 apart from the lack of metal absorption redwards of the Ly\( \alpha \) emission line.

As described in \S 3.4, we use the mock spectra as a benchmark for the PCA fit quality on the red-side \( (\lambda_{\text{rest}} > 1216\,\text{Å}) \) of the spectra — we automatically accept all fits with absolute flux error, \( |\delta F| \), less than the 95th percentile of the \( |\delta F| \) distribution measured from the mocks (Figure 5). For the fits with larger \( |\delta F| \) that require visual inspection, we use the mocks as a visual guide for what constitutes a good fit.

It is clear from Figure 6 that the mean-flux regulated continuum, \( C_{\text{MF}} \), is a corrected version of the PCA fit, \( C_{\text{PCA}} \), in several cases, the initial PCA continuum, \( C_{\text{PCA}} \), appeared unphysical (e.g. dipping below the peaks of the forest). These were rectified by the mean-flux regulated fit, \( C_{\text{MF}} \).

We place this on a more quantitative footing by comparing the fitted continua, \( C_{\text{fit}} \), to the ‘true’ continuum, \( C_{\text{true}} \), which is known by construction in the mock spectra. We define the continuum fitting residual,

\[
\delta C(\lambda_{\text{rest}}) \equiv \frac{C_{\text{fit}}(\lambda_{\text{rest}})}{C_{\text{true}}(\lambda_{\text{rest}})} - 1. \quad (7)
\]

We can then carry out MF-PCA fits on large numbers of mock spectra to obtain statistics on the continuum fitting errors as a function of S/N and quasar redshift. In Figure 7(a), we show the residuals from fitting 1000 mock spectra in two bins of signal-to-noise, S/N, and quasar redshift, \( z_{\text{QSO}} \). The orange lines show the residuals as a function of wavelength, \( \delta C(\lambda_{\text{rest}}) \), binned into restframe 1Å bins from a subset of 100 mocks. The dashed lines show the \( 1 - \sigma \) dispersion of the residuals estimated from bootstrap resampling at each 1Å wavelength bin, while the dotted lines show the 10th and 90th percentile at each wavelength. Figure 7(a) represents one of the worst case scenarios — the signal-to-noise deteriorates rapidly with decreasing wavelength. This causes a large scatter in the flux of Ly\( \alpha \) forest even when averaged over large segments, introducing more errors to the mean flux regulation process.

At moderate signal-to-noise (S/N = 6–10, Figure 7(b)), the situation is significantly better. The \( 1 - \sigma \) dispersion of the fit residuals are well under 10%, and 6–7% in the central portion of the fitted region. Many of the residuals are flat to within a few percent across the Ly\( \alpha \) forest region, indicating that the PCA-fitting has successfully accounted for the shape of the Ly\( \alpha \) continuum. About one-tenth of the fitted continua are badly fit, with badly-predicted continuum shapes and/or residuals greater than 10%.

We also calculate the mean bias, \( \overline{\delta C}(\lambda_{\text{rest}}) \), of the residuals in Figure 7. Averaged over \( \sim 10^9 \) spectra, the MF-PCA technique have a low bias of < 1%, although this not include any systematics errors in the \( \langle F \rangle(z) \) measurement used to constrain the overall continuum levels.

To quantify the overall fit quality on each mock spectrum, we use the RMS of the continuum residuals evaluated over \( \lambda_{\text{rest}} = 1041 - 1185\,\text{Å} \):

\[
(\delta C)_{\text{rms}} = \left[ \frac{\int \left( \frac{C_{\text{fit}}(\lambda_{\text{rest}})}{C_{\text{true}}(\lambda_{\text{rest}})} - 1 \right)^2 d\lambda_{\text{rest}}}{\int d\lambda_{\text{rest}}} \right]^{1/2}. \quad (8)
\]

Figure 8 shows the median RMS error from runs of 1000 mocks as a function of redshift, for 4 different S/N bins. At lower redshifts, the RMS error is relatively high for the low-S/N spectra because the mean flux regulation is affected by the increased noise levels near the blue-end of the SDSS spectra at \( \lambda_{\text{obs}} \sim 4000\,\text{ Å} \). As the observed Ly\( \alpha \) forest region clears the blue end of the spectra, the RMS error decreases to a minimum at \( z_{\text{QSO}} \approx 3.0 \). It then rises with redshift at \( z_{\text{QSO}} > 3 \) due to the increasing variance in the Ly\( \alpha \) forest, which adds to the error in the mean-flux regulation. At fixed redshift, the median RMS decreases with S/N as might be expected. Below \( z_{\text{QSO}} \approx 3 \), it drops below 5% RMS for moderate signal-to-noise (S/N ~ 5) and asymptotes to \( \sim 3 - 4\% \) RMS for the S/N > 10 spectra.

To estimate the contribution from various sources of error in the MF-PCA fitting, we also carried out the mean-flux regulation directly on the simulated Ly\( \alpha \) forest skewers without introducing a quasar continuum, or adding pixel noise. In other words, we directly fit the function Eq. 3 to the mean flux evaluated over 3 bins in each skewer. The RMS error in the continuum from this estimate is shown as the dashed line in Fig. 8. For \( z_{\text{QSO}} = 2.3 \) quasars, the RMS error contribution from Ly\( \alpha \) forest variance is about 1.5% ; this increases to 4% at \( z_{\text{QSO}} = 4.0 \). This suggests that even in the limit of high-S/N, errors in the continuum shape from PCA fitting contributes 1–2% to the overall RMS continuum error.

### 4.3. Power-law+Mean Continuum Fitting

To place the above results in context, we carry out another set of continuum fits on the mock spectra, using the continuum model

\[
C_{\text{mean}}(\lambda_{\text{rest}}) = f_{1280} \times \mu(\lambda_{\text{rest}}) \times \left( \frac{\lambda_{\text{rest}}}{1280\,\text{Å}} \right)^{-\alpha}, \quad (9)
\]

in which the mean spectrum, \( \mu(\lambda_{\text{rest}}) \), is multiplied with a power-law, \( \lambda_{\text{rest}} \propto \lambda^{-\alpha} \), and \( f_{1280} \) is the flux normal-
Fig. 7.— Continuum fitting errors from MF-PCA fitting on mock Ly$\alpha$ forest spectra, plotted as a function of quasar restframe wavelength for (a) $2 \leq S/N < 4$ and $2.5 \leq z_{QSO} \leq 2.7$; (b) $6 \leq S/N < 10$ and $2.9 \leq z_{QSO} \leq 3.1$. In both cases, 1000 mock spectra were generated and continuum-fitted. The grey lines represent a random subset of continuum-fitting errors from 100 fits. We also show the overall bias (solid line), the dispersion (dashed line), and the 10th/90th percentiles (dotted line) of the errors as a function of wavelength. Note that Figure (a) represents a regime with the worst MF-PCA continua, and is truncated at the lower-limit of the observed spectral range, $\lambda_{obs} = 3840$ Å.

Fig. 8.— Median RMS continuum fitting error, $\langle |\delta C| \rangle$, from fitting 1000 mock spectra, calculated for different redshifts, $z_{QSO}$, and signal-to-noise, $S/N$, on the red-side of the spectrum. The rise in the low-$S/N$ values of $\langle |\delta C| \rangle$ at low-$z_{QSO}$ is due to the increase noise levels at the blue end ($\lambda_{obs} \lesssim 4000$ Å) of the SDSS spectra, while the overall increase in $\langle |\delta C| \rangle$ with redshift is due to the increase in the variance of the Ly$\alpha$ forest. The dashed-line shows the RMS fitting error in the absence of continuum structure and noise.

Fig. 9.— Same as Figure 7(b), but for the power-law+mean spectrum continua, $C_{\text{mean}}$ (Equation 9), fit to 1000 mock spectra. Note the larger errors in comparison with the MF-PCA residuals. The median RMS error from the continua shown in Figure 9 is $\langle |\delta C| \rangle_{\text{rms}} = 0.13$, which is worse than any of the $[S/N, z_{QSO}]$ bins evaluated in Figure 8.

4.4. Residual Continuum Power

The RMS continuum fitting error is not the most important quantity for studies of the 1-dimensional Ly$\alpha$ forest flux power spectrum,

$$P_F(k) = 2\pi \int_0^\infty \delta(k)\delta^*(k)dk,$$  \hspace{1cm} (10)
McDonald et al. (2006) had used a mean continuum higher-S residual power by $\sim$10% compared to $S/N \approx 0.014$ km$^{-3}$s, indicated by the solid red vertical line in Figure 10. We thus estimate the residual power in $C_{\text{mean}}$, at this scale at which continuum power interferes with $P_F(k)$ measurements. We can then look for the points in the $C_{\text{MF}}$ residual power spectra with the same limiting power (red arrows in Figure 10). Note that this assumes that the Lyα forest power is constant whereas the Lyα forest power decreases with scale, but the change is gradual. For our rough estimates, we can approximate it as constant over small logarithmic intervals.

The corresponding limiting values of $k$ (red dotted lines) are significantly smaller than for $C_{\text{mean}}$. This suggests that MF-PCA continuum fitting could allow the Lyα forest flux power spectrum to be measured at larger scales than previously possible. For $S/N = 6 - 10$ spectra, the lower $k$-limit is now $k = 0.0007$ km$^{-3}$s. This corresponds to a doubling of the accessible comoving scales: $r = 2\pi/k \approx 90$ h$^{-1}$ Mpc at $z = 2.75$ compared to $r \approx 45$ h$^{-1}$ Mpc in the McDonald et al. (2006) study, where these distances are calculated assuming a standard flat ΛCDM cosmology with $h = 0.7$, $\Omega_m = 0.28$ and with a $w = -1$ cosmological constant. Even for noisy ($S/N = 2 - 4$) spectra, the accessible scale has been increased significantly to $r \approx 65$ h$^{-1}$ Mpc.

The new continuum-limited scales approach the $\sim 100$ h$^{-1}$ Mpc baryon acoustic oscillation (BAO) scale at moderate signal-to-noise ($S/N \gtrsim 6$). In Figure 10 the black vertical dot-dot-dash-dotted line indicates the wavelength of the first BAO peak, calculated from the prescription in Eisenstein & Hu (1998). Even though future BAO measurements in the Lyα forest are expected to be carried out in 3-dimensions (McDonald & Eisenstein 2007), the increase in accessible modes along the lines-of-sight will improve the robustness and precision of the measurements.

5. RESULTS AND CONCLUSION

5.1. Public Release of Continua

We have carried out mean-flux regulated PCA (MF-PCA) continuum fitting on 12,069 quasar spectra from the SDSS DR7 catalog. The continua in the spectra range $1030 \AA < \lambda_{\text{rest}} < 1600 \AA$ have been made publicly available, and can be downloaded via anonymous FTP.

The IDL fitting code took ~ 0.5 seconds per spectrum (including file input/output) on a single processor core of a 3.0 GHz Intel Quad Core desktop with 2 GB of RAM, allowing the entire SDSS DR7 Lyα forest sample to be fitted in about two hours.

Since we expect the MF-PCA technique to provide a good continuum fit only when there is a good PCA fit redwards of the quasar Lyα line, the fitted spectra have been visually inspected to verify the fit quality in the $\lambda_{\text{rest}} = 1216 \AA - 1600 \AA$ wavelength region. Approximately 89% of the spectra had reasonable PCA fits, and these have been flagged as such in the publicly available continua, although we recommend that users of the continua should make their own cuts on the fit quality.

\footnote{ftp://ftp.astro.princeton.edu/lee/continua/}
Approximately 30\% of the spectra were better fitted by the low-redshift Suzuki et al. (2005) templates, while the rest were better fitted by the Paris et al. (2011) templates. This is qualitatively as expected, since there is greater overlap by the Paris et al. (2011) templates in the luminosity distribution of the SDSS quasars.

From the mock spectra analysis of the fit quality in § 4 we have estimated the continuum fitting error at each pixel within the Ly\(\alpha\) forest, as a function of quasar redshift and spectral signal-to-noise. However, the errors have significant covariances, therefore it would be too unwieldy to provide the full error estimates for each spectrum although we can provide them upon request.

It is worth noting that although we have made a choice on the mean-flux of the Ly\(\alpha\) forest in our fits (Eq. 6), it is straightforward for users to rescale each fitted continuum to their favorite \((F)(z)\).

5.2. Empirical Tests of Fit Quality

While we have studied the performance of MF-PCA continuum fitting on mock spectra in § 4 it is difficult to empirically constrain the quality of the fits. One possibility is to compare a small subset of the data with high-resolution, high-S/N spectra of the same objects. However, even with high-resolution spectra, it is questionable whether there are sufficient transmission peaks in the forest to adequately constrain the continuum shape. Faucher-Giguère et al. (2005) have shown that accurate fitting of the quasar continuum is difficult beyond \(z \approx 2.5\). Furthermore, most high-resolution spectra are obtained from echelle spectrographs with uncertain spectrophotometry, so it would be tricky to directly compare quasar sightlines which have been observed in both SDSS and high-resolution echelle spectrographs.

However, it is possible to get a sense of the efficacy of our MF-PCA continua by stacking large numbers of spectra. This cancels out the Ly\(\alpha\) forest power from individual sightlines, and allows the underlying continuum shape to be seen, albeit lowered due to the mean Ly\(\alpha\) absorption.

Recall that the PCA coefficients, \(c_j\), parametrize the shape of the quasar spectra. Therefore, if our continuum-fitting technique works, quasars with similar \(c_j\) measured from \(\lambda_{\text{rest}} > 1216\) Å should have similar-looking continua within the Ly\(\alpha\) forest region. Thanks to the large number of spectra in our SDSS sample, it is possible to stack \(\sim 10^2\) spectra with similar values of \(c_j\) to recover the collective shape of their Ly\(\alpha\) forest continua.

We can select subsamples of quasars based on their values of \(\sigma_1 \equiv c_1/\lambda_1\) and \(\sigma_2 \equiv c_2/\lambda_2\), where \(\lambda_1 = 7.563\) and \(\lambda_2 = 3.604\) are the standard deviations of \(c_1\) and \(c_2\), respectively, in the low-redshift HST eigenspectra Suzuki (2005). These two principal components account for approximately 80\% of the total variance in the low-redshift quasar templates. We limit ourselves to spectra with \(S/N > 3\) pixel\(^{-1}\), and which have been visually inspected to be decent fits redwards of \(\lambda_{\text{rest}} = 1216\) Å. We also select quasars with \(z_{\text{QSO}} > 2\) in order to ensure reasonably complete coverage of the Ly\(\alpha\) forest. Within a subsample, each spectrum is first normalized near \(\lambda_{\text{rest}} = 1280\) Å and rebinned into a common wavelength grid with \(\Delta\lambda_{\text{rest}} = 1\) Å bins before being stacked. The same procedure is carried out on the MF-PCA continuum fitted to each spectrum, to obtain a mean MF-PCA continuum for the subsample.

In Fig. 11 we show 4 subsamples from our SDSS sample with different \([\sigma_1, \sigma_2]\) with respect to the low-redshift eigenspectra. Redwards of 1216 Å, we see that the least-squared PCA procedure generally does a good job of fitting the emission lines, although there are inaccuracies in fitting N V \(\lambda 1214\) and Si II \(\lambda 1300\). Bluewards of 1216 Å, the stacked spectrum appears to have a similar shape to the fitted continua, although the overall flux level is depressed due to the mean Ly\(\alpha\) absorption.

We can make a more direct comparison between the stacked spectra and the fitted Ly\(\alpha\) forest continua by correcting each observed Ly\(\alpha\) forest pixel by its mean flux (using Equation 6) before stacking. The mean-flux corrected Ly\(\alpha\) forest is shown as the disembodied red line in Fig. 11. It is gratifying to see that the stacked MF-PCA continua generally agrees well with the stacked Ly\(\alpha\) forest spectra. Our technique can clearly account for the diversity in quasar continua: spectra with clear emission-line features (Fig 11h) and those with smooth continua (Fig 11i) are well differentiated. Because we have corrected each Ly\(\alpha\) forest pixel by the same mean-flux (Eq. 6) which we have used to carry out the MF-PCA fits, we expect the amplitude of the corrected Ly\(\alpha\) forest stacks, in \(\lambda_{\text{rest}} = 1041\) Å – 1185 Å, to match those of the stacked MF-PCA continua, but the tilt and shape of the continuum bears testament to the success of the technique. In addition, since the MF-PCA continua shown in Fig 11 were a subset which used the Suzuki et al. (2005) quasar templates, this suggests that it was appropriate to use low-redshift templates to fit some of the \(z_{\text{QSO}} \gtrsim 2\) SDSS spectra.

5.3. Conclusions

We have introduced mean-flux regulated PCA (MF-PCA) continuum fitting, a new technique for predicting the Ly\(\alpha\) forest continuum in low-S/N spectra. In tests on mock spectra, we have found that MF-PCA can predict the continuum at the 8\% RMS level in SDSS spectra with \(S/N \sim 2\) at \(z = 2.5\), and \(< 5\%\) RMS in \(S/N \gtrsim 5\) spectra. This is a significant improvement over the \(\sim 15\%\) RMS continuum errors previously achievable in low-S/N spectra. We are making available MF-PCA continuum fits for 12,069 Ly\(\alpha\) forest spectra from the SDSS DR7 quasar catalog. The MF-PCA technique also significantly reduces the Fourier power from continuum-fitting residuals by a factor of a few in comparison with a mean continuum. This will allow a concomitant increase in the accessible scales for Ly\(\alpha\) forest flux power spectrum measurements.

This improved continuum-fitting accuracy will significantly increase the value of low-S/N Ly\(\alpha\) forest data. For example, the ongoing Baryon Oscillations Spectroscopic Survey (BOSS) will obtain Ly\(\alpha\) forest spectra from \(\sim 150,000\) quasars at \(z_{\text{QSO}} \gtrsim 2\), with the aim of measuring the baryon acoustic oscillation feature in the Ly\(\alpha\) forest absorption across different quasar sightlines. The typical signal-to-noise (\(S/N \sim 2\)) of BOSS spectra will be even lower than that of SDSS (\(S/N \sim 4\)), therefore we expect the MF-PCA technique to contribute significantly to the utility of the BOSS data.
Fig. 11.— Stacked SDSS Lyα forest spectra (black) and similarly-stacked MF-PCA continuum fits, plotted for narrow selections of the first two PCA eigenvalues, \(\sigma_1\) and \(\sigma_2\). The red curve shows the 1041Å < \(\lambda_{\text{rest}}\) < 1185 Lyα forest region of the spectra which have been corrected by the mean-flux prior to stacking. The agreement of the MF-PCA stacks with the mean-flux corrected Lyα forest stacks show that the MF-PCA is doing a good job of predicting the shape of the Lyα forest continuum.
There are several ways in which the current work could be improved. The Suzuki et al. (2005) PCA templates with which we have used to fit some of the spectra were derived from a low-redshift quasar sample which may not be a perfect descriptor of the SDSS data (although the test in §4 shows that it does a reasonable job). In addition, while the $Q_{\text{QSO}} \sim 3$ [Paris et al. (2011)] templates were indeed obtained from SDSS quasars, they used a high-luminosity subset which are not representative of the full SDSS luminosity distribution. Furthermore, the hand-fitting technique which they had used to obtain continua from these spectra cannot be used for the lower-luminosity (and hence lower-S/N) quasars.

However, with a large data set such as SDSS or BOSS, it is possible to regard the Lyα forest absorption within individual spectra as a noise term which cancels out with sufficiently large numbers of template spectra. This will allow new eigenspectra to be generated from the data itself, although each individual spectrum will need to be corrected by its mean flux before being included in the eigenspectrum solution. In the near future, we will work on this technique to generate new eigenspectra from the BOSS data.

The other issue with the MF-PCA fitting is that it requires an assumed mean-flux, $\langle F \rangle (z)$ for the Lyα forest. This is not ideal, as the evolution of the mean-flux is an important observable of the Lyα forest. This could in principle be overcome by solving simultaneously for the mean-flux of the Lyα forest and the continuum-fitting parameters for the individual spectra, using maximum-likelihood techniques. This would allow large Lyα forest data sets to be continuum-fitted and studied in a fully self-consistent fashion.

The authors thank Michael Strauss and Xavier Prochaska for useful discussions and comments, and to Isabelle Paris for providing the data from her mean-flux measurement.

Funding for the SDSS and SDSS-II has been provided by the Alfred P. Sloan Foundation, the Participating Institutions, the National Science Foundation, the U.S. Department of Energy, the National Aeronautics and Space Administration, the Japanese Monbukagakusho, the Max Planck Society, and the Higher Education Funding Council for England. The SDSS Web Site is http://www.sdss.org/

The SDSS is managed by the Astrophysical Research Consortium for the Participating Institutions: the American Museum of Natural History, Astrophysical Institute Potsdam, University of Basel, University of Cambridge, Case Western Reserve University, University of Chicago, Drexel University, Fermilab, the Institute for Advanced Study, the Japan Participation Group, Johns Hopkins University, the Joint Institute for Nuclear Astrophysics, the Kavli Institute for Particle Astrophysics and Cosmology, the Korean Scientist Group, the Chinese Academy of Sciences (LAMOST), Los Alamos National Laboratory, the Max-Planck-Institute for Astronomy (MPIA), the Max-Planck-Institute for Astrophysics (MPA), New Mexico State University, Ohio State University, University of Pittsburgh, University of Portsmouth, Princeton University, the United States Naval Observatory, and the University of Washington.
